Abstract

Do parties target individuals or groups? This is a question fundamental to understanding clientelism, yet the literature does not offer an answer. This paper argues that depending on certain conditions, brokers largely target either individuals or groups. The conditions relevant to this decision include how individuals discount the future, the presence of political pressure to secure higher levels of electoral support, and the density of the concentration of poor individuals. Under specific combinations of these three factors, individuals are more identifiable, which in turn makes individual targeting cheaper. Other combinations provide spillover effects, leading brokers to engage in group targeting. Though the theory I outline focuses on targeting, this paper also argues that structural factors should be considered as explanations of vote-buying. Structural factors are one of the few observables upon which brokers can base their decisions regarding where to invest in clientelism. Using survey data from Brazil, the paper exploits variations in personal incomes within contexts of differing levels of poverty. I find that political parties engage in segmented or ad-hoc strategies, targeting individuals when identifiability is high and groups when there are economies of scale. Importantly, non-poor individuals can also be offered clientelism.

Please consider downloading the last version of the paper [here](#).

I thank participants of the XXXII Latin American Studies Association Conference, The Southern Political Science Association meeting, The Western Political Science Association meeting and the 2014th Graduate Conference at the Political Science Dpt., Rutgers U. This work was partially funded by the Center for Latin American Studies at Rutgers University. I am thankful to the School of Arts and Sciences and the Department of Political Science for their travel grants.

There is no agreement on when, how and why parties choose to aim clientelistic practices at individuals or groups. The distributive politics and vote-buying literatures have traditionally pursued one of two approaches. On the one hand, the former has mostly focused on group targeting, usually districts or provinces.¹ In this literature, incumbent parties deliver public-sector jobs or construction projects contingent on the support of *groups* of people. On the other hand, the latter has typically focused on *individuals* and their characteristics, such as their socio-economic or electoral profiles. I share Carlin and Moseley [2015, 14]'s diagnosis, in that "[e]xisting research looks almost *exclusively* at individuals' socio-economic and, specially, electoral profile [and] [y]et our knowledge of who parties target remains incomplete."² Moreover, the decision to investigate group-based and/or individual-based targeting seems to be attributable to distinct research designs rather than theory. For example, ethnographers most generally focus on individuals, while others have traditionally focused on groups (though not exclusively).³ What is most concerning, however, is that it is relatively assumed or implied that individual and group clientelistic targeting strategies are interchangeable. In this paper I systematize the process of deciding who to target by arguing it is a function of three mechanisms: individuals' discount factors explained by income levels, the incentives of clientelistic brokers to rely on spillover effects caused by the nesting structure of individuals (i.e. whether individuals are nested in poor or non-poor contexts), and brokers' incentives to engage in clientelism explained by higher electoral pressures and political competition. Given the nested structure of the argument and the empirics, I am able to disentangle the effects of "being poor" and "living in a poor area" on clientelistic targeting. One important implication is that I am able to explain why clientelistic parties target their resources to both poor *and* non-poor individuals, an empirical regularity that to the best of my knowledge has been unexplored so far (see Figure 1).

Perhaps the area in which there is the most agreement among scholars is on the relationship between poverty and vote-buying.⁴ For example, Brusco et al. [2004], Stokes et al. [2013] and Nazareno et al. [2008] explain that since the poor derive more utility from immediate transfers than the risky returns associated with future policy packages, clientelistic political parties *only* target the poor. In fact, Weitz-Shapiro [2014, 12] explains that "[a]lmost *universally*, scholars of clientelism treat and analyze the practice as an exchange between politicians and their poor clients."⁵ However, this canonical predictor has recently been challenged. Szwarcberg [2013] "challenges the assumption [that brokers] with access to material benefits will always distribute goods to low-income voters in exchange for electoral support," while Gonzalez-Ocantos et al. [2012] and Holland and Palmer-Rubin

¹See Dixit and Londregan [1996], Khemani [2015] and Calvo and Murillo [2004].

²Emphasis is mine.

³See for example Scott [1972], Auyero [2000], Szwarcberg [2013] and Weitz-Shapiro [2012] and Gonzalez-Ocantos et al. [2012]. I thank Ezequiel González Ocantos for this suggestion.

⁴See Calvo and Murillo [2004], Weitz-Shapiro [2012], Kitschelt [2000] and Kitschelt and Altamirano in Carlin et al. [2015, ch. 10]. Following Brusco et al. [2004, 67], I define vote-buying as "the proffering to voters of cash or (more commonly) minor consumption goods by political parties, in office or in opposition, in exchange for the recipient's vote." In the rest of this note, I use clientelism and vote-buying interchangeably.

⁵Emphasis is mine.

Figure 1: *Individual Wealth and Vote-Buying in Brazil*

[2015] found that income (measured at the individual level) had little or no effect on vote-buying. Why is contemporary scholarly work reporting null findings for poverty, traditionally the *most* important predictor of vote-buying? I propose an alternative theoretical framework centered on contextual and structural factors. Since brokers need to secure the highest possible electoral returns for every unit invested in clientelism, brokers target individuals who can be held accountable. My claim is that clientelistic accountability will be higher when individuals are identifiable, that is, when poor individuals live nested in non-poor contexts, and vice-versa.

One often-considered contextual factor in the literature is the size of the community where clientelism takes place. Large-sized communities impose principal-agent problems. If an individual's vote is bought, he or she may be tempted to accept the benefit and then vote for his or her preferred candidate anyway, and this incentive increases linearly with the size of the community where the individual is nested in. Several scholars have then argued that brokers prefer smaller groups because individuals nested in small communities should defect less.⁶ One problem, however, is that it is not clear how political parties gain enough electoral returns from such an expensive strategy. This strategy implies that local brokers monitor, target, enforce and mobilize electoral support on a one-to-one basis.⁷ However, the theoretical challenge is that this method seems to be extremely expensive given the relatively small number of votes brokers can secure one by one. Moreover, the cost of this strategy increases linearly with the size of the targeted population. The brokers' production-possibility frontier cannot be shifted upwards either, as monitoring capacities

⁶See for an overview Stokes [2005, 323], Brusco et al. [2004], Kitschelt and Wilkinson [2006, 10] and Magaloni [2008, 67]. Rueda [2016] finds support for this hypothesis in Colombia. Similarly, see Bratton [2008] for Nigeria and Gingerich and Medina [2013, 456] for Brazil.

⁷For example, Stokes [2005] argue that brokers develop skills that allow them to infer whether individual clients in small-sized communities voted for their party by *looking at them in the eyes*. For the Brazilian case, similar ethnographic evidence is suggested in Gay [1993, 1998].

are bounded. Simply put, at some point party machines run out of brokers. When brokers need to secure large amounts of electoral support, specially when political competition is high, they turn to group targeting strategies relying on the spillover effects of clientelism. In these contexts, clientelism mobilizes electoral support from *actual* and *potential* beneficiaries, a mechanism that I explain later on in the paper.

Civic associations might help solve some of the challenges large-sized groups present to brokers. As (most) brokers cannot observe individual electoral behavior in low-information environments, they resort to alternative methods that allow them to make safer inferences. For example, [Schaffer and Baker \[2015\]](#) explain that clientelism is “socially multiplied” as party machines target individuals “who are opinion-leading epicenters” in informal situations or “partisan networks,”⁸ in what has been called “organization buying.”⁹ And if parties buy “turnout,”¹⁰ then they will most probably target associations too, as “citizens immersed in clientelistic networks [...] have a higher probability of voting than the rest.”¹¹ The positive relationship between group-membership and clientelism is intuitive. However, what has not been explored yet is whether clientelism is explained by the “nesting” that results from group membership or the “organization buying” such membership facilitates. Membership in local grass-roots associations is common when low-income individuals are nested in highly poor contexts. Keeping coordination costs constant, groups typically form to address problems that otherwise would be too costly to solve outside of the group. If this is the case, formal group *membership* should be spuriously related to clientelism. In other words, we need to know whether clientelism is associated with group membership *itself*, or with the density of the poor in the contexts in which these groups exist. While I find that group membership does have a positive effect on clientelism, I find that the density of the poor in a given area has even more explanatory power.

In an important paper, [Weitz-Shapiro \[2012\]](#) finds that in several Argentine municipalities, higher levels of political competition mixed with low socioeconomic indicators led to more clientelism. However, in her paper losses are conceptualized in terms of “moral costs.”¹² These types of costs have been theorized in the literature very recently. For example, [Carlin and Moseley \[2015\]](#) argue that citizens endowed with more democratic values feel more “moral repugnance” to clientelism, [Vicente \[2014\]](#) explains that vote-buying practices have an “immoral/illegal connotation,” and [Gonzalez-](#)

⁸Calvo and Murillo [2013].

⁹Stokes et al. [2013, 250-251]. [Holland and Palmer-Rubin \[2015, 16\]](#) explain that when “parties lack their own brokerage networks [they seek] to capitalize on organizational networks instead.” Similarly, [Rueda \[2015, 13\]](#) argues that parties tend to target very specific civic associations of “seniors and associations of single mothers, organizing trips to recreational centers outside the city where all their expenses are covered.” *Paradoxically*, the stronger the civic society, i.e. the more organized it is, the more clientelism.

¹⁰Nichter [2008].

¹¹Carreras and Castaneda-Angarita [2014, 7].

¹²[Weitz-Shapiro \[2012\]](#) argues that non-poor individuals are more likely to condemn clientelism “due to self-interest or because of *moral* concern[s]” (emphasis is mine). That being said, ‘self-interest’ refers to the idea that what is being distributed through clientelism is *discounted* from the pool of resources theoretically available to be spent on policy packages. And that *is* an economic cost.

Ocantos et al. [2012] find that individuals wanting to avoid social stigma usually do not give truthful answers asked directly about clientelism. However, it is not clear if individuals who benefit from vote-buying really *understand* these kinds of ‘costs.’ In fact, Gonzalez-Ocantos et al. [2014] find that while the concrete benefits obtained through vote-buying are generally well understood, “the abstract societal costs of such exchanges are often distant from the every-day world in which clientelistic relationships are formed.” Building on these intuitions, I incorporate the economic advantages/costs of targeting individuals or groups, and model the frequency of clientelism mediated by different degrees of political competition.

WHEN DO PARTIES TARGET INDIVIDUALS AND WHEN GROUPS?

Brokers will have incentives to engage in individual targeting when targets are easier to *identify*. Identifiability helps brokers keep targeted individuals electorally accountable. Higher levels of identification also reduce the costs of enforcing the clientelistic contract, especially when it comes to monitoring. Whereas individual targeting is the safest bet a broker can make, this mechanism is more expensive as it requires him to have close relationships with clients. The capacity brokers have to identify potential clients does not come from third-party sources (i.e. membership in civic groups/associations). One of the few observables brokers have at their disposition is how *noticeable* individuals are in their respective contexts. Should brokers engage in individual targeting, they would rather visit highly noticeable *poor* households in *non-poor* neighborhoods. As these households stand out in non-poor contexts, it is easy for brokers to notice whether they need construction materials, whether there are wakes to which they could contribute flowers or birthday parties to which they could bring cakes. Poor households need not be close to each other, they just need to be *visible* enough for brokers to detect their needs. Consequently, income alone does not play an independent role. Rather, what is important is how individual incomes interact with their respective poverty context, making individuals more or less identifiable. Individuals will be more noticeable when non-poor individuals are nested in poor areas (quadrant 1 in Table 1) and when poor individuals are nested in non-poor areas (quadrant 4 in Table 1).

	Non-Poor Individuals	Poor Individuals
High Competition	Poor Areas , <i>identifiable, individual targeting</i>	Poor Areas , <i>spillover effects, group targeting, cheap vote-buying</i>
Low Competition	Non-Poor Areas , <i>group targeting, expensive vote-buying, lack of checks and balances, embezzlement</i>	Non-Poor Areas , <i>identifiable, individual targeting</i>

Table 1: *Strategy Set: Group v. Individual Targeting*

When poor individuals are nested in poor areas, or vice-versa, individual targeting is no longer efficient. Since individuals are masked by their environments, identifiability is hard to achieve, increasing the cost of this strategy. In these circumstances, depicted in quadrants 2 and 3 in [Table 1](#), group targeting is more efficient as it relies on the *spillover* effects provided by larger concentrations of individuals. Group targeting works because it also mobilizes electoral support from potential clients, that is, those who have not received benefits yet. For example, [Auyero \[2000, 65\]](#) describes the case of *Alfonsina* in Argentina. *Alfonsina* was part of the brokers' inner circle and received a job as a cleaning lady in a public school. As the broker explained to her before getting the job, *Alfonsina* had to be *patient* because as a member of 'the circle,' she was in the pool of potential beneficiaries; it was only a "matter of time" until she could get the job. Building on this intuition, my argument presents two ideal types: *actual* and *potential* beneficiaries. The former receive particularistic benefits "today" and vote for the broker's candidate "tomorrow," while the latter do not receive benefits today (in the expectation of receiving them in the future) but *still* vote for the broker's candidate. Actual beneficiaries want to remain actual beneficiaries; thus, they keep supporting the broker's candidate. Potential beneficiaries want to become actual beneficiaries, but are uncertain when that might happen; as a result, they keep supporting the broker's candidate. This mechanism requires the broker's ability to not allow the transaction costs of switching strategies to be lower than what it costs clients to wait to be benefited. In other words, brokers need to take care of their reputation and deliver benefits. [Zarazaga \[2014, 14\]](#) finds that *brokers and voters' interests are aligned. Since the flow of resources to voters is dependent on their brokers' electoral success, if the broker loses the election and is replaced, clients do not know what/if the new broker will get them benefits. A new broker may access to fewer resources or choose to distribute them to other people, and brokers often remind voters about this.* Hence, no matter what the type is, both of them keep voting for the broker's party. Given that the poor are risk-averse, potential beneficiaries are better-off waiting (and voting for the broker's party) than defecting. In a slightly different subject, [Magaloni \[2008, 20\]](#) explains that in non-democratic contexts voters have incentives to keep voting for the incumbent government, *even when they oppose it*.¹³ The cost of switching brokers (or defecting) is very high since it also involves building from scratch relationships of confidence with the new broker. Therefore, reputation costs keep clients disciplined and brokers exploit these self-enforced compliance dynamics. Vote-buying is also targeted at non-poor individuals as in quadrant 3. Though vote-buying has decreasing returns to scale in non-poor individuals,¹⁴ low levels of political contestation give local politicians more "room to move," allowing them to divert local resources into more expensive means of targeting (embezzlement). This situation is sustained by the

¹³The Mexican PRI lasted as long as it did not because of electoral fraud but because voters supported the "known devil." As Magaloni explains, hegemonic parties survive when they are able to sustain long-term economic growth and a constant supply of clientelistic transfers.

¹⁴Buying votes from non-poor individuals gets more expensive as income increases.

very low levels of political opposition.

CASE SELECTION, RESEARCH DESIGN AND DATA ANALYSES

This paper tests the effects of individual income, the effects of being nested in *communities* with different poverty structures (“density of the poor”), and the effect of being exposed to different levels of political competition, on receiving clientelism. Brazil is a good case because its poverty structure is such that it is possible to find low-income individuals nested in non-poor areas (and vice versa). This case is also interesting from an institutional perspective. The Brazilian electoral system *incentivizes* clientelism. Several factors such as multimember districts with open lists and the institution of the *candidato nato*,¹⁵ “clearly [makes] Brazil one of the most personalistic systems of democratic governance.”¹⁶ In fact, [Gingerich \[2014, 290\]](#) finds that vote-buying drastically changed electoral results, concluding that “[v]ote brokerage can still pay electoral dividends in contemporary Brazil.”

To test this hypothesis, I use survey data from 2010 from [the Latin American Public Opinion Project \[LAPOP\]](#).¹⁷ Though the LAPOP survey provides a question for income, people who are somewhat better off than their neighbors but live in poor areas may not “feel” poor. If this is the case, this could confound the results. Additionally, when answering the questioner, individuals might not want to reveal their true incomes (either because it is too low or too high). Following the advice of [Córdova \[2008\]](#) and [Córdova and Seligson \[2009, 2010\]](#), a relative wealth index (RWI) was constructed.¹⁸ Using principal component analyses, this index measures wealth based on actual assets weighted by how common those assets are. Different indexes were constructed for urban and rural contexts. [Figure 1](#) plots the distribution of the combined index separated by clientelism. To measure the density of the poor, I followed a strategy similar to that of [Weitz-Shapiro \[2012\]](#), measuring the degree of poverty at the municipal level. Using information from the 2010 Brazilian census,¹⁹ a variable was constructed that measures the percentage of individuals who live on less than half of the minimum wage in a given municipality. Given that the municipality of residence for each individual in the LAPOP survey is recorded, I was able to merge the census percentage with the LAPOP dataset. The size of the poor group measured at the municipal level serves as a good proxy to capture the size of the poor group. It is important to stress that the unit of analysis is the individual, and that this variable captures the economic context in which each individual

¹⁵ “[R]ule that removed parties’ control over the nominations process and let an electoral legislator decide to run on any party ticket.” See [Carlin et al. \[2015, Chapter?\]](#).

¹⁶ [Carlin et al. \[2015, Chapter?\]](#).

¹⁷ “I thank the Latin American Public Opinion Project (LAPOP) and its major supporters (the United States Agency for International Development, the United Nations Development Program, the Inter-American Development Bank, and Vanderbilt University) for making the data available.” The sample consists of five strata representing the five main geographical regions of Brazil. Each stratum was further sub-stratified by urban and rural areas.

¹⁹ Official data comes from the Bureau of Statistics of Brazil [IBGE](#).

Figure 2: *Distribution of the Density of the Poor*

lives. And just like other scholars in the past have tested the effect of being nested in rural areas,²⁰ this paper focuses on another class of contextual variable. Although the size of the poor group was originally a semi-continuous variable, it had to be dichotomized at the median (29%) to be able to construct a matched sample, which I justify and explain below. Figure 2 shows the continuous distribution dichotomized at the median (dashed line). Finally, to measure political competition, the paper follows Weitz-Shapiro [2012]. Using official electoral data from the 2008 municipal elections,²¹ a variable was constructed that measures the percentage of seats that are not controlled by the mayor's party in a given municipal council.

There is a built-in lack of relationship between “being poor” and “living in a poor municipality,” confirming that Brazil is in fact a good case to test this theory. Figure A1 in the Appendix shows that the unmatched/raw dataset had already embedded low levels of correlation between these two variables (0.44).²² Using matching methods, I am able to further break this relationship. Matching is a two-stage process. In the first stage the analysts preprocesses the data, seeking to break any systematic relationship between, in this case, the density of the poor and the wealth index.²³ Matching does so by deleting observations for which matches cannot be found.²⁴ The idea is to obtain a good covariate balance as in Figure OA2 in the Online Appendix, to then estimate any appropriated statistical model.²⁵ From a statistical standpoint, preprocessed datasets are less

²⁰See for example Brusco et al. [2004] and Stokes [2005]. Both of them use the log of population, which is a proxy for urban/rural.

²¹Data from the *Tribunal Superior Eleitoral*.

²²The figure shows that for both the matched and raw datasets, “being poor” and “living in a poor municipality” are not confounded, as it is possible to find poor individuals living in non-poor areas, and viceversa.

²³King et al. [2011]

²⁴The final procedure matched 761 individuals living in the low-density poverty condition with 676 individuals living in the high-density poverty condition.

²⁵The idea is that the propensity of being exposed to the “high density of the poor” (the ‘propensity score’) has a similar distribution in both ‘treated’ and ‘control’ groups. It is important to say that, despite the language, I do not

model-dependent²⁶ and prevent analysts from making extreme counterfactuals.²⁷ Table A2 and Table A1 in the Appendix provide summary statistics for both the matched and raw datasets.²⁸ The preprocessed data used in the matching approach has 54 municipalities while the raw data used in the GPS approach (which I explain below) has 54 too. Figure 3 lists the municipalities and shows which ones are considered “high” or “low” in terms of the density of the poor after the dichotomization process. The figure also shows that there exists considerable variance in income/RWI in both high and low poverty density conditions.²⁹

It could be argued that dichotomizing the **density of the poor** variable at the median is an arbitrary decision. While there have been theoretical advances regarding general treatment effects regimes for continuous or semi-continuous response doses,³⁰ algorithms with the ability to match continuous treatment variables are not common. To obtain covariate balance in a non-parametric in the first stage but *without* dichotomizing the variable of the **density of the poor**, I also use the original (i.e. *continuous*) **density of the poor** variable to construct a generalized propensity score GPS.³¹ The score is used to *weight* each observation in the model. Besides matching on and weighting by income, I also included the following variables to match on/weighting by: municipal opposition, municipal population and individual involvement in civic associations.

The dependent variable is clientelism. To measure it, I use the question that asks if *a candidate or someone from a political party offered [the respondent] something, like a favor, food, or any other benefit or thing in return for [her/his] vote or support*. Subjects could answer that this had happened *often, sometimes* or *never*. Carreras and Irepoglu [2013] and Holland and Palmer-Rubin [2015] use the same dataset and outcome variable. As they explain, the question did not ask whether respondents *took* the offer, hence it should not be an important source of social desirability bias. For statistical reasons, I dichotomized this variable, combining the alternatives *often* (n = 91) and *sometimes* (n = 150), leaving *never* (n = 1196) unchanged.³²

The next control variables were considered. Perception of corruption was included to hold constant the effect of respondents who declared clientelistic activity when in reality they were referring to corruption scandals.³³ Brokers usually target civic associations. Following Holland and Palmer-Rubin [2015, 28], who use the same dataset/year, an additive index to measure civic

claim any causal relationship in this paper.

³¹See Imbens [2004], Guardabascio and Ventura [2014] and Imai and Ratkovic [2014]. To generate the weighting vector, I used the `CBPS` R package (see Fong et al. [2014]).

³²These numbers come from the matched dataset.

³³I thank Cesar Zucco for this suggestion.

Figure 3: *Distribution of Observations by Municipality, Wealth Index and Density of the Poor*

participation (*Political Involvement*) was created.³⁴ Some have also found group size to be important. Using the census data, a variable to measure population size at the municipal level was included. I also included an urban/rural dummy. A variable to capture party identification (*Political Id.*) was included. Higher levels of democratic support should be negatively associated with clientelism. To control for that, a variable measuring democratic support was included. [Gonzalez-Ocantos et al. \[2014\]](#) find that schooling plays a negative role on clientelism; hence, I control for educational levels too.

Observations are clustered on a number of important factors such as levels of municipal political competition, municipal poverty and municipal population size. In order to account for these clustering effects, I use a generalized estimating equations approach. GEE were introduced by [Liang and Zeger \[1986\]](#) to fit clustered, repeated (i.e. correlated) and panel data. This method is especially efficient when the data are binary.³⁵ GEE models are similar to random effects models³⁶ in that they allow observations to be nested in hierarchical structures. This method requires analysts to parameterize the working correlation matrix. Though [Hedeker and Gibbons \[2006, 139\]](#) explain that “the GEE is robust to misspecification of the correlation structure,”³⁷ [Hardin and Hilbe \[2013, 166\]](#) point out that “[i]f the observations are clustered (not collected over time), then [...] the exchangeable correlation structure” is the most appropriate working correlation matrix. Given that the data do not follow a panel but rather a clustered structure, the exchangeable correlation matrix was specified

³⁴This variable was constructed by adding the frequency of attendance at religious meetings, community improvement meetings and political party meetings (variables `cp6`, `cp8` and `cp13`, respectively).

³⁵[Hanley et al. \[2003\]](#).

³⁶[Gardiner et al. \[2009\]](#).

³⁷[Carlin et al. \[2001, 402\]](#) argue that “[r]elatively minor differences in estimates may arise depending on how the estimating equations are weighted, in particular within the generalized estimating equation (GEE) framework.” [Westgate and Burchett \[2016\]](#) and [Gardiner et al. \[2009, 227\]](#) make the same point.

for all models.

While this method is very flexible, GEE estimates remain uninterpretable in practice,³⁸ making regression tables useless from a substantive standpoint. In this case, the problem is even more severe due to the interactive hypotheses being tested in this paper. The main hypothesis is tested by fitting a parameter for the multiplicative term between the variables **wealth index**, **political competition** and **high density**. Methodologists agree on “not interpret[ing] the coefficients on the constitutive terms,” as they lack substantive meaning.³⁹ These problems get more complex when it comes to generalized models as a series of challenges arise. As [Ai and Norton \[2003\]](#) explain, *(1) the interaction effect could be nonzero, even when the estimation says it is zero, (2) the statistical significance of the interaction effect cannot be tested with a simple t-test on the coefficient of the interaction term, (3) the interaction effect is conditional on the independent variables, [...] and (4) the interaction effect may have different signs for different values of covariates.* [Brambor et al. \[2005, 74\]](#) offers the same advice, namely “one cannot determine whether a model should include an interaction term simply by looking at the significance of the coefficient on the interaction term.” Given that cross-partial derivatives are not advisable either, simulation methods are required.⁴⁰ Particularly, I follow the simulation approach introduced in [King et al. \[2000\]](#). This procedure samples via simulation from the point estimates, generating a new and larger distribution. That is, taking the single estimated parameters (the regression coefficients), I construct a distribution of estimated values for each coefficient. Relying on the central limit theorem, with enough sampling draws, the new simulated distribution is a transformation that approximates with a great degree of precision the (uninterpretable) coefficients. Subsequently, means and uncertainty measures can be constructed for each of these distributions. From a substantive standpoint, simulation methods also allow for sampling new distributions at different values of the independent variables. This will be important in simulating the expected value of clientelism for different “profiles,” such as *non-poor* individuals nested in *high-poor* dense municipalities in contexts of *high* political competition, etc.

Since it is “impossible to evaluate conditional hypotheses using only the information provided in traditional results tables,”⁴¹ I focus instead on the substantive results from the simulation methods. However, I still present the raw results in [Table A3](#) in the Appendix.⁴² Analogous to [Table 1](#), in [Figure 4](#) I simulate the predicted probabilities of being targeted using both the matched and weighted models. The horizontal panel depicts simulations for the upper (“non-poor,” 75%) and lower (“poor,” 25%) quartiles of the continuous **wealth index** variable. In turn, the vertical panel shows the simulated values for the maximum (100%) and minimum (43%) values of the **municipal**

opposition index. Each quadrant shows simulations for individuals nested in poor municipalities (*high density of the poor*) and non-poor municipalities (*low density of the poor*). Each profile shows two simulated probability distributions (with 95% confidence intervals), one for the matched sample and one for the weighted sample.⁴³

Figure 4 suggests that brokers engage in *individual* targeting when individuals are identifiable. That is, when individuals are poor *but* nested in low-poor density municipalities (quadrant 4, with a probability of being targeted 22%)⁴⁴ and when individuals are not poor but nested in high-poor density municipalities (quadrant 1, with a probability of being targeted 24%). This suggests that political competition incentivizes motivated brokers to engage in vote-buying regardless of personal income when political competition is high. *Group* targeting is more efficient in quadrant 2, supporting the spillover effects hypothesis. When municipal mayors are politically challenged, brokers target *groups* of poor individuals in poor municipalities (quadrant 2, 26%). Non-poor individuals nested in low-poor density municipalities but exposed to lower levels of political competition (quadrant 3) are still offered some vote-buying. In these contexts there are less political competition and less checks and balances, having incumbents more “room to move.” Even when politicians are not in need of more electoral support, they still engage in this expensive form of vote-buying.

Figure 5 shows a plot divided in two panels. Panel **a** shows the simulated expected probabilities

⁴³In the case of the weighted sample which uses the continuous version of the size of the poor variable, “low density” represents the lower quartile while “high density” the upper quartile.

⁴⁴Matched sample.

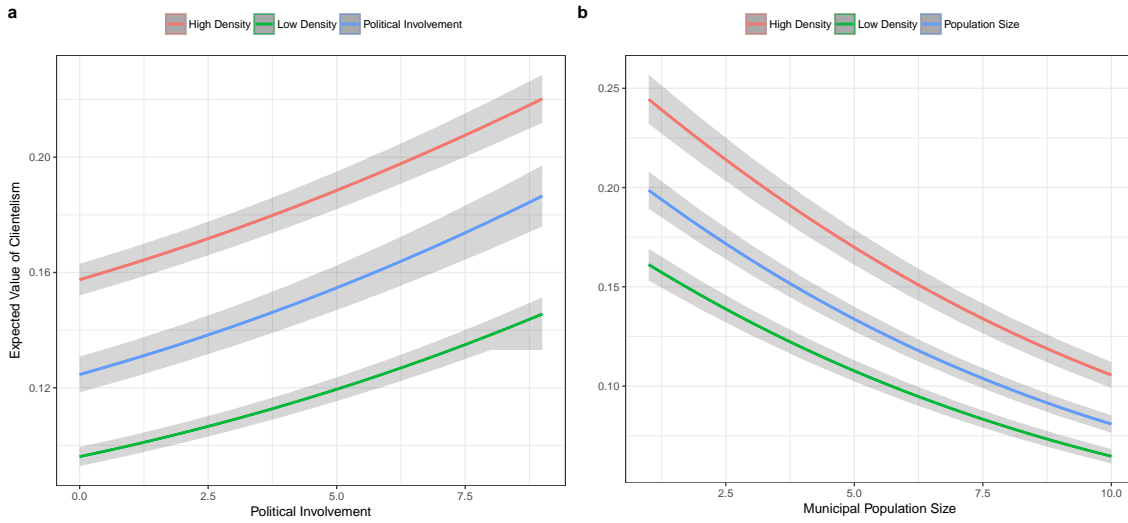

Figure 5: *Simulated Expected Probability of being Targeted: Political Involvement and Population Size*

of being targeted at different levels of political involvement. As the blue lines suggest, individuals who participate in civic associations have higher probabilities of being targeted. This is in line with findings in previous research.⁴⁵ However, once I decompose these effects, being nested in high-poor density areas contributes substantially more to the model. These differences are statistically significant. Panel **b** shows the probability of being targeted at different increments of the size of the population. In line with the literature, I also see that this relationship is negative⁴⁶ However, the effect of being nested in high-poor density municipalities outperforms the effect of population size, suggesting spillover effects (even when income/wealth and political competition are held constant). What this exercise tells us is twofold. First, it is important to consider macro explanations of vote-buying, as they shape brokers' incentive structures when deciding when and who to target.

Discussion

In sum, the article systematized different profiles that made clientelism more likely. Depending on how individuals discounted the future (income), pressures to secure higher levels of electoral support (electoral competition) and how dense (or not) the concentration of poor individuals was, brokers will tend to engage in either *group* or *individual* targeting. Individual targeting is more effective when individuals are more noticeable. Group targeting is more effective when the size of the poor group provides spillover effects multiplying the resources invested in clientelism. I also made the case that structural/contextual factors are one of the few, and perhaps only, observable characteristics

⁴⁵Schaffer and Baker [2015], Carreras and Castaneda-Angarita [2014, 7], Calvo and Murillo [2013], Holland and Palmer-Rubin [2015, 16] and Rueda [2015].

⁴⁶Stokes [2005, 323], Kitschelt and Wilkinson [2006, 10], Magaloni [2008, 67], Rueda [2016], Bratton [2008] and Gingerich and Medina [2013, 456].

brokers have available to make strategic decisions about where to invest in clientelism. Particularly, I focused on the density of the poor. Since these factors shape the broker's cost/benefit analysis, the literature should consider them more carefully.

APPENDIX

Table A1: *Summary Statistics: Raw Sample*
